# Constitutive relations in dense granular flows

John J. Drozd and Colin Denniston

Department of Applied Mathematics, The University of Western Ontario, London, Ontario N6A 5B8, Canada

(Dated: September 12, 2009)

We use simulations to investigate constitutive relations in dry granular flow. Our system is comprised of poly-disperse sets of spherical grains falling down a vertical chute under the influence of gravity. Three phases or states of granular matter are observed: a free-fall dilute granular gas region at the top of the chute, a granular fluid in the middle and then a glassy region at the bottom. We examine a complete closed set of constitutive relations capable of describing the local stresses, heat flow, and dissipation in the different regions. While the pressure can be reasonably described by hard sphere gas models, the transport coefficients cannot. In contrast to a hard sphere gas, transport coefficients such as viscosity and heat conductivity increase with decreasing temperature in the fluid and glassy phases. The glass exhibits signs of a finite yield stress and we show that the static sand pile is a limit of our glassy state.

#### I. INTRODUCTION

The attempt to accurately describe stresses in granular matter has a long history. The problem is difficult due to the energy dissipation in the system that makes it hard for granular systems to achieve a true thermodynamic equilibrium. This makes the application of normal equilibrium statistical mechanics techniques problematic. Bagnold's early work [1] on sheared granular suspensions identified three different regimes of flow behavior, the macroviscous dominated by the interstitial fluid, the transitional, and the grain inertia regime where the effects of the interstitial fluid are negligible (similar to dry cohesionless granular materials). Savage and collaborators [2–5] worked to derive relationships based on a kinetic theory approach and describe things in terms of a dimensionless parameter R which is the ratio of mean shear characteristic velocity to the r.m.s. velocity (velocity fluctuations). Durian and Menon [6] measured a closely related quantity in a dry granular flow in a chute and found that the velocity fluctuations were proportional to the mean flow velocity to the 2/3 power (i.e.  $\delta v \sim v^{2/3}$ ) suggesting that  $R = v/\delta v$  may not be a natural parameter for granular flows [7] as it is not likely to be a constant for any particular flow. Simulations indicate that even the  $\delta v \sim v^{2/3}$  is not true locally but is more a statement about global stress/energy balances (i.e. true only when suitably averaged over quite heterogeneous regions) [8]. This suggests a need to get measurements of stresses, strains, and other transport phenomena on a local level, something that is ideally suited to simulation

The study of stresses and forces in static granular system has also been studied extensively. Force chain models [9] demonstrated the wide distribution of forces in granular packs. The consideration of the effects of directed force propagation suggests various constraints that can be placed on the stress tensor in granular packs [10–14]. Edwards and collaborators attempted to consolidate these ideas on a statistical mechanics based on an av-

eraging over ensembles of mechanically stable packings [15, 16]. This, however, is predicated on the assumption that the distribution of mechanically stable packings of spheres is relatively flat. There are suggestions that this might not be the case [17]. It is therefore desirable to generate configurations in a physically meaningful way implying a coupling between the dynamics responsible for creating static states (i.e. before it became static) and the static model itself is required. Thus simulations of granular dynamics with a well defined static limit is desirable.

Apart from adopting specific models, if we concentrate on the basic physics of momentum conservation, mass conservation and energy conservation, this does not provide us with enough equations to fully solve for local density, velocities, and temperature. In order to solve for these quantities, the stress tensor and heat flux need to be expressed in terms of these local variables in order to "close" the equations (i.e. have the same number of equations and unknowns). This prompts us to studying various constitutive relations to provide these necessary additional constraints. With this aim in mind, we have performed simulations of gravity driven dense granular flow in three dimensions to compare and test constitutive pressure, stress and energy relations of granular matter.

The binary, hard sphere collision model used for our simulations is similar to that used in [8, 18], but for illustrative purposes a typical snapshot from one of our simulations is shown in Fig. 1(a). We will reiterate a brief description of our model in the next paragraphs but for more details one can refer to references [8, 18].

In our simulation, frictionless, rigid spherical grains are dropped in from the top of a rectangular chute and fall under the influence of gravity. There are flat walls at the left and right (x-direction) of the chute and periodic boundary conditions at the front and back (z-direction). At the bottom of the chute (y=0), grains are reflected with a probability p (typically p=90%). Particles transmitted through the bottom are replaced at the top of the chute in order to maintain steady-state. Particles reflect

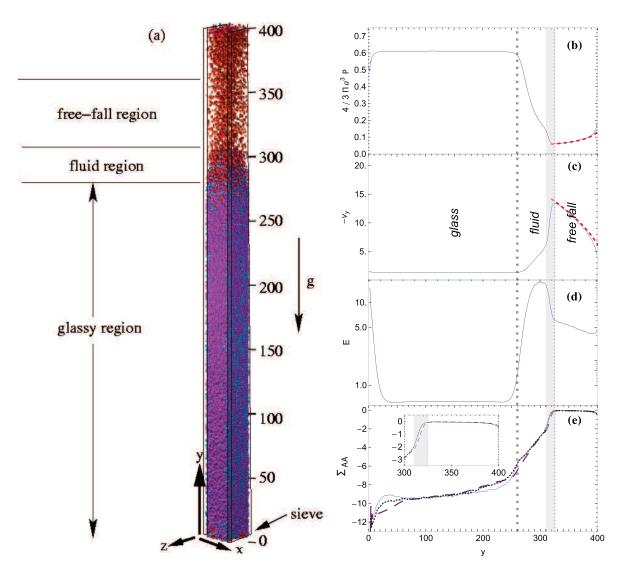

FIG. 1: (a) Section of a simulation involving 43 200 grains with 15 % polydispersity. The system size is  $32a \times 32a \times 400a$ . There are reflective walls at x=0 and  $x=L_x$ , periodic boundary conditions in the z-direction, and a finite probability of reflection at the bottom of the chute (at y=0) with an asymptotic coefficient of restitution  $\mu_0=0.97$ . Time-averaged density (volume fraction) in (b) and y- velocity in (c) down the center of a 3D chute. The short dashed lines are analytic calculations of density and  $v_y$  in the free-fall region (described in text). (d) The total kinetic energy  $E=\frac{1}{2}\rho v^2+\frac{3}{2}\rho T$  and (e) stress tensor components  $\sigma_{xx}$  (solid line),  $\sigma_{yy}$  (dashed line) and  $\sigma_{zz}$  (dotted line). The measurements for plots (b), (c), (d) and (e) were taken down the center of the chute.

off the walls of the chute with a partial loss, typically 10% in their vertical (y) velocity. This is essential as experiments show [19, 20] that much of the column weight is supported by the walls.

Particles in our simulation undergo binary collisions where their momenta are transferred along the line joining their centers. Specifically, the velocities after collision  $\dot{\mathbf{r}}_1'$  and  $\dot{\mathbf{r}}_2'$  in terms of the velocities before collision,  $\dot{\mathbf{r}}_1$  and  $\dot{\mathbf{r}}_2$ , are

$$\begin{pmatrix} \dot{\mathbf{r}}_{1}' \\ \dot{\mathbf{r}}_{2}' \end{pmatrix} = \begin{pmatrix} \dot{\mathbf{r}}_{1} \\ \dot{\mathbf{r}}_{2} \end{pmatrix} + \frac{(1+\mu)}{(m_{1}+m_{2})} \begin{pmatrix} -m_{2} & m_{2} \\ m_{1} & -m_{1} \end{pmatrix} \begin{pmatrix} \dot{\mathbf{r}}_{1} \cdot \mathbf{q} \\ \dot{\mathbf{r}}_{2} \cdot \mathbf{q} \end{pmatrix} \mathbf{q},$$

$$(1)$$

where  $\mathbf{q} = (\mathbf{r}_2 - \mathbf{r}_1)/|\mathbf{r}_2 - \mathbf{r}_1|$ , and  $\mu$  is the coefficient of restitution. Such collision models of granular flow have a long history [3, 5].  $\mu$  is a velocity-dependent restitution coefficient described by the phenomenological relation[21, 22],

$$\mu(v_n) = \begin{cases} 1 - (1 - \mu_0) (v_n/v_0)^{0.7} &, v_n \le v_0 \\ \mu_0 &, v_n \ge v_0. \end{cases}$$
 (2)

Here  $v_n$  is the component of relative velocity along the line joining the grain centers,  $\mu_0$  is the asymptotic coefficient at large velocities, and  $v_0 = \sqrt{2ga}$  [23]. Equation (2) effectively makes the ball collisions become more elastic as the collisions become weaker as observed experimentally [24, 25]. Scaled units are given in footnote

[26].

In previous work [8, 18] we examined both mono- and poly-disperse mixtures of spheres. Here we simulate only systems with 15% poly-disperse particles. In this context, a polydispersity of 15% means that the standard deviation of a particle radius is 0.15 if the mean is 1 using a gaussian distribution of radii. Poly-disperse particles achieve a truly glassy state, and here we are interested in testing and comparing constitutive relations in the glassy state, in addition to the free-fall and fluid states. Mono-disperse or nearly mono-disperse particles experiencing shear often increase in order and crystallize [8, 18, 27], and it is beyond the scope of this paper to examine the approach to the crystallized state in detail, although we did touch upon such details in previous work [8, 18].

A typical steady-state configuration of our simulation is shown in Fig. 1(a). The steady-state density (plotted as a volume fraction), velocity, energy, and diagonal stresses from our simulation for this typical configuration were measured all down the center of the channel and are plotted in Figs. 1(b), (c), (d) and (e), respectively. The orientation of the x, y and z axes is shown at the bottom of the visualization in Fig. 1(a).

As indicated by the labels and vertical dashed lines in Figs. 1(b)-(e), there are three regions, which we label as a glassy region, a fluid region and a free fall region. These labels were justified in our previous work [8, 18]. In the free fall region the grains accelerate at  $1\,g$  and collisions do not have a significant impact on their kinetics [8, 18]. In the liquid region the density is sufficiently high that collisions mix the grains, but the distribution of collision times are exponential, meaning that collisions are largely independent. In the glass region, the collision time distribution is a power-law and thus collisions are not independent and as a result there are collisions at a wide range of time scales [18].

It is important to note that the relative sizes of the glassy, fluid and free-fall regions vary depending on the coefficient of restitution used. As expected, the lowest asymptotic coefficient of restitution of 0.9 resulted in the smallest fluid region, an intermediate asymptotic coefficient of restitution of 0.95 resulted in a larger fluid region, and the largest asymptotic coefficient of restitution of 0.99 resulted in the largest fluid region for the same sized column. The existence of transition regions between the free-fall, fluid and glassy states was demonstrated in previous work [8]. The transition region between the freefall region and the fluid region is indicated by the vertical gray shaded stripe in Figs. 1(b-e). Unless noted, the results shown in this paper use an asymptotic coefficient of restitution of 0.97 so we can study one of the wider transition regions. A wider fluid region clearly shows a kink in the free-fall to fluid transition region in the data profiles as shown in Figs. 1(b)-(e). It is interesting to note that the kink at this transition in the density and velocity profiles lines up with the peak in the kinetic energy and inflection point in the stress profiles as shown in Figs. 1 (d) and (e). This peak marks the boundary between the fluid region and the free-fall to fluid transition region.

## II. CONTINUUM EQUATIONS

Our simulation evolves over discrete binary collisions. In our simulation, we average various physical properties based on these discrete events over time and space. We resolve our  $32a \times 32a \times 400a$  chute over a fine volume grid composed of  $1a \times 1a \times 1a$  cubes. This resolution was chosen to scale with the size of the particles of mean radii a=1. This allows us to map our discrete system onto a time-averaged continuum set of fields. We will now begin by describing the continuum equations describing the average density,  $\langle \rho \rangle$ , velocity  $\langle \vec{v} \rangle$  and energy  $\langle E \rangle$  that we would expect our system to map onto. To simplify the notation, even though the measured properties in our simulation are quantities averaged in time and over the translational invariant z-direction, we omit the angled brackets  $\langle \cdot \rangle$  in the conservation equations that follow. Typical averaging times are 600 to 1000 time units after 200 time units of equilibration. The equilibration time of 200 time units is equivalent to the typical lifetime of a particle in the chute for the slower moving systems (i.e. the time from when it enters at the top to falls out the bottom).

#### A. Conservation equations

In this section, we will describe the continuum equations of conservation of mass, momentum and energy that we will attempt to map our simulation results onto. We will describe how the physical terms in these equations can be measured directly from our simulation.

The continuity equation for mass gives us one equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0. \tag{3}$$

Momentum conservation requires that

$$\partial_t(\rho v_\alpha) + \partial_\beta(\rho v_\alpha v_\beta) = \partial_\beta \sigma_{\alpha\beta} + \rho g_\alpha, \tag{4}$$

where  $\sigma_{\alpha\beta}$  is the stress tensor, and all  $v_{\alpha}$  and  $v_{\beta}$  refer to first moments of the velocity distribution. This gives us three Navier-Stokes equations.

The time averaged stress tensor can be directly measured in our simulation using the microscopic form of the 3D stress tensor [28]:

$$\sigma_{\alpha\beta} = \sigma_{\alpha\beta}^{\mathbf{kinetic}} + \sigma_{\alpha\beta}^{\mathbf{collision}} \tag{5a}$$

$$= -\langle \rho \left( v_{\alpha} - \langle v_{\alpha} \rangle \right) \left( v_{\beta} - \langle v_{\beta} \rangle \right) \rangle \tag{5b}$$

+ 
$$\frac{1}{t} \sum_{collisions} -\frac{1}{2} (1 + \mu) (\mathbf{\dot{r}_1} - \mathbf{\dot{r}_2}) \cdot \mathbf{\hat{q}} (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}).$$

The  $\frac{1}{2}$  accounts for the double counting of collisions in the sum (we count the transfer from particle 1 to 2 and the transfer from 2 to 1).

Our fifth equation is an equation describing the energy conservation in our system

$$\partial_t (E) + \partial_\alpha (v_\alpha E + F_\alpha) = I + \rho g \cdot \mathbf{v}$$
 (6)

The (kinetic) energy is

$$E = \frac{1}{2}\rho v^2 + \frac{3}{2}\rho T. (7)$$

Note that  $v^2 = \langle v \rangle^2$  in the first term and

$$T = \frac{1}{3}\delta v^2 = \left(\langle v_x^2 \rangle + \langle (v_y - \langle v_y \rangle)^2 \rangle + \langle v_z^2 \rangle\right)/3 \tag{8}$$

is the granular temperature. The energy, E, from our simulation is plotted in Fig. 1(d). **F** is the non-convective energy flux and  $\alpha$  refers to the x, y or z component.

An important component of the non-convective energy flux  $\mathbf{F}$ , is the collision energy flux,  $\mathbf{F_c}$ . Part of the energy flux is related to the coherent transfer of momentum, that is, the work done by the stress tensor and the other part is the heat flux. We can measure the energy transfered between grains in a collision using Eq. (1)[28] to get

$$\delta \mathbf{F_c} = \frac{1+\mu}{m_1 + m_2} \left[ m_1 \left( \dot{\mathbf{r}}_1 \cdot \mathbf{q} \right)^2 - m_2 \left( \dot{\mathbf{r}}_2 \cdot \mathbf{q} \right)^2 \right] \mathbf{q}.$$
 (9)

Averaging over time gives the collision energy flux as

$$\mathbf{F_c} = \frac{1}{t} \sum_{collisions} \delta \mathbf{F_c}.$$
 (10)

Similarly, we can easily use Eq. (1) to calculate the dissipation, I from the kinetic energy lost in each collision,

$$\delta I = -\frac{1 - \mu^2}{2(m_1 + m_2)} \left( m_1 \dot{\mathbf{r}}_1 \cdot \mathbf{q} - m_2 \dot{\mathbf{r}}_2 \cdot \mathbf{q} \right)^2.$$
 (11)

If we average  $\delta I$  over the collisions that occur in a small cell  $(1 \times 1 \times L_z)$  of our simulation, and if we also average  $\delta I$  per unit time (effectively multiplying by the collision frequency  $f_c$ ), we arrive at the average dissipation rate I which is the remaining term in Eq. (6).

Equations (3), (4) and (6) give us five equations (in the static limit), but there are six unknown stress values, namely the diagonal stresses  $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\sigma_{zz}$ , and using the fact that the stress tensor is symmetric, we have the shear stresses  $\sigma_{xy} = \sigma_{yx}$ ,  $\sigma_{xz} = \sigma_{zx}$  and  $\sigma_{yz} = \sigma_{zy}$ . We need six constitutive equations to solve for these six unknown stress values. Similarly, all the terms in Eq. (6) can be measured directly from a simulation, however they cannot be predicted ahead of time without relating the **F** and I to the density, velocities, or energy by means of two additional constitutive relations. The dissipation and heat flux will be examined in more detail in sections II E and II G.

#### B. Stress and energy balance

In the previous section we described the conservation equations that are applicable to our system. In the upcoming sections we will examine these conservation equations in detail applying them to the different regions of our simulation. In this section we will examine the balance of stress and energy in the fluid, glass and free-fall regions.

First examine Eq. (4) in the liquid and glassy regions. The stress tensor cannot be ignored in these regions, even as a first approximation. If we assume in Eq. (4), that the time derivative is zero as we are in steady state, and if we assume that the kinetic terms,  $\partial_{\beta} (\rho v_{\alpha} v_{\beta})$  are negligible (as is observed by the low acceleration values in the glassy and in part of the fluid region in Fig. 2(c) in reference [8] and in Fig. 1(d) in reference [18]), we arrive at

$$\partial_x \sigma_{yx} + \partial_y \sigma_{yy} = -\rho g_y, \tag{12}$$

where  $g_y = -g < 0$  in this orientation.

Figures 2(a) and (b) show the balance of the weight,  $-\rho g$  and stress gradients  $\partial_x \sigma_{yx} + \partial_y \sigma_{yy}$  in the fluid and glassy regions, respectively. There are *very* significant differences between how these terms are balanced in the liquid and glassy regions. We find that the pressure gradient  $\partial_y \sigma_{yy}$  is the dominant term supporting the weight in the fluid region. This is consistent with what one would expect in a simple fluid where the pressure would be a function of depth,  $P = \rho gy + constant$ . In contrast, in the glassy region we find that the gradient in the shear stress,  $\partial_x \sigma_{yx}$  is the dominant term supporting the weight. Here, as in [18], we can conclude that in the glassy region behaves like a solid in this sense.

Now that we have looked at the stress balance in the fluid and glassy regions, we examine the balance in the free-fall region. Taking the y component of the Navier-Stokes Eq. (4), we have

$$\partial_y \left( \rho v_y^2 \right) = \partial_y \sigma_{yy} + \rho g_y, \tag{13}$$

where  $g_y = -g < 0$  in this orientation. Figure 2(c) shows the balance of the weight,  $\rho g$  and stress gradients  $\partial_y \sigma_{yy} - \partial_y \left(\rho v_y^2\right)$ . In the free-fall region the pressure gradient,  $\partial_y \sigma_{yy} \approx 0$ , and the kinetic term,  $-\partial_y \left(\rho v_y^2\right)$ , contributes solely to balance the weight,  $\rho g$ .

Finally, we explore the energy balance Eq. (6) in all three regions. We can assume that the time partial derivatives are negligible since we are in steady state and that the derivatives in the periodic z direction are also negligible. Note that the only significant energy fluxes are in the x and y directions and  $\delta v_x^2 \approx \delta v_y^2 \approx \delta v_z^2$  and thus we can say that  $T \approx \delta v_y^2$  (the isotropic assumption is not strictly correct but is a reasonable first approximation in the bulk regions [8]). Using these assumptions together with Eq. (6), we finally arrive at the energy equation

$$\nabla \cdot \mathbf{F} = I + \rho q v_{u},\tag{14}$$

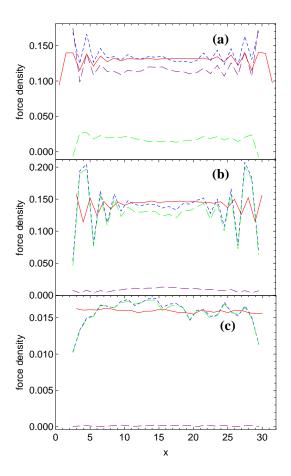

FIG. 2: Plot of force densities  $\partial_y \sigma_{yy}$  (dot-dashed line),  $\partial_x \sigma_{yx}$  (long dashed line),  $\partial_x \sigma_{yx} + \partial_y \sigma_{yy}$  (short dashed line) and the weight  $-\rho g_y$  (solid line) in (a) the fluid region and (b) the glassy region versus the width x for a 400-height column using an asymptotic coefficient of restitution  $\mu_0$  of 0.97 and probability of reflection p = 90%. (c) Plot of force densities  $\partial_y \sigma_{yy}$  (dot-dashed line),  $-\partial_y \rho v_y^2$  (long dashed line),  $(\partial_x \sigma_{yy} - \partial_y \rho v_y^2)$  (short dashed line) and the weight  $-\rho g_y$  (solid line) in the free-fall region.

where we have used the following relation to separate the kinetic and collision energy flux [4]

$$\mathbf{F} = \mathbf{F_c} - \frac{1}{2} \langle \rho \left( v_{\alpha} - \langle v_{\alpha} \rangle \right) \left( v_{\beta} - \langle v_{\beta} \rangle \right) \rangle v_{\beta}$$
 (15)

The left and right sides of Eq. (14), as directly measured from our simulation, are plotted in Fig. 3. The clear agreement in the free fall, fluid and glass regions shows that all the assumptions made to this point are reasonable.

Thus we see that particularly the stress balance distinguishes the different states of the system but in order to actually solve the conservation equations we need to relate the measured stress, dissipation, and energy flux to the density, velocities, and granular temperature. This is the focus of the rest of the paper.

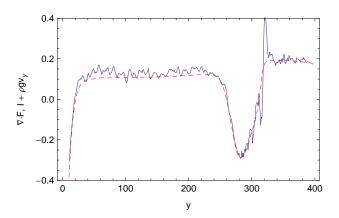

FIG. 3: (a) Plot of the components of the energy equation from Eq. (14) in the free-fall region. The solid line is the left side of the equation,  $\nabla \cdot \mathbf{F}$ , and the dashed line is the right side of the equation,  $I + \rho g v_y$ .

#### C. Pressure

In our discussion of stress balance in the previous section, we demonstrated the role of the pressure gradient in balancing the weight, particularly in the fluid and somewhat less importantly in the glass. In this section, we will examine several equations of state for pressure for the glassy and fluid regions of our system. In a simple fluid the pressure is normally defined as

$$P = -\frac{1}{3}Tr(\sigma), \qquad (16)$$

and the diagonal stresses  $\sigma_{\alpha\alpha}=-P$ . However, as is already clear from Fig. 1(e) the diagonal stresses are not equal everywhere, so we will examine the pressure tensor diagonal components as

$$P_{\alpha\alpha} = -\sigma_{\alpha\alpha}.\tag{17}$$

As jamming is approached, Salsburg and Wood [29] used a free volume approximation to suggest that the pressure in a classical (conservative) hard sphere system approaches

$$P = (\rho T)(1 - (\phi/\phi_c)^{1/D})^{-1}, \tag{18}$$

They also gave an asymptotic approximation (as  $\phi \to \phi_c$ ) of Eq. (18) as

$$P = D(\rho T)(1 - \phi/\phi_c)^{-1}.$$
 (19)

In Eqs. (18) and (19) D is the dimension and  $\phi$  is a volume packing fraction

$$\phi = \frac{4}{3}\pi a^3 \frac{\rho}{m},\tag{20}$$

where m is a mean grain mass, and  $\phi_c$  is a random close-packed density. For monodisperse spheres,  $\phi_c$  is known to be  $\sim 0.64$ . As our spheres are polydisperse  $\phi_c$  is unknown and must be fit. Typically it is slighly lower than

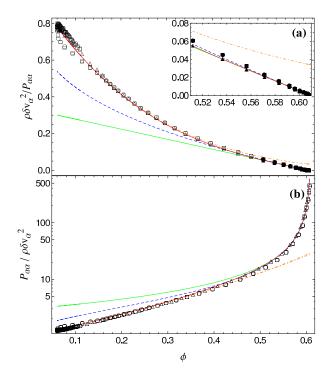

FIG. 4: (a) Plot of  $\rho \delta v_x^2/P_{xx}$  (squares),  $\rho \delta v_y^2/P_{yy}$  (triangles), and  $\rho \delta v_z^2/P_{zz}$  (circles) versus  $\phi$ . Also plotted are the result from Eq. (19) (solid green (bottom) line), Eq. (18) (blue dotted (middle) line), and Eq. (23) (orange dot-dashed (top) curve).  $\phi_c$  is the observed close-packed density in the glassy region and  $\delta v_\alpha^2 = \langle (v_\alpha - \langle v_\alpha \rangle)^2 \rangle$ . (b) Inverse of data in (a). In both plots closed symbols indicate the glassy region and open symbols the fluid regions. The data is for a  $32 \times 32 \times 400$  simulation with an asymptotic coefficient of restitution  $\mu_0 = 0.97$  and a probability of reflection at the bottom of the chute p = 0.9. The red curve through the data is described in the text. (Color Online)

the monodisperse case at 0.61. Normally these expressions involve Boltzmann's constant and the absolute temperature, which is not relevant for dissipative granular materials so we follow standard convention and replace  $k_BT$  with the granular temperature in Eq. (8), something that would be entirely equivalent in a conservative hard sphere system. Also, the true form of Eq. (19) has an additional constant of order 1, but literature usually quotes this equation suppressing the constant.

As can be seen in Fig. 4 both Eqs. (18) and (19) do well as the close-packed density is approached in the glassy region, but they give higher pressures than what we observed in our simulation at lower densities in the fluid regions. As expected, the asymptotic approximation Eq. (19) is worse in the fluid region than the true free-volume expression Equation (18), although both disagree with our simulation data in the fluid region. Similar effects are found in simulations of elastic hard sphere packings [30].

At low densities, a more appropriate approach to studying the equation of state of a hard sphere fluid is to use a virial expansion:

$$\frac{P}{\rho T} = 1 + B_2 \phi + B_3 \phi^2 + \dots, \tag{21}$$

where again  $\phi$  is the volume packing fraction proportional to density and  $B_i$  are the virial coefficients. For hard spheres, the Carnahan-Starling [31] equation of state for a hard sphere fluid uses a rescaled virial series solution of the Percus-Yevick equation [32] for hard spheres which is an approximate integral equation for determining the radial distribution function of a fluid. It uses the rescaled virial series

$$\frac{P}{\rho T} = \frac{1 + c_2 \phi + c_3 \phi^2 + \dots}{(1 - \phi)^3},$$
 (22)

where  $c_i$  are related to the virial coefficients  $B_i$ . The Carnahan-Starling [31] equation of state is written as

$$\frac{P}{\rho T} = \frac{\left(1 + \phi + \phi^2 - \phi^3\right)}{\left(1 - \phi\right)^3}.$$
 (23)

Both the Carnahan-Starling equation, Eq. (23), as well as the virial expansion to 12 coefficients, as derived in [33, 34], are shown in Figure 4 (dash-dotted lines, indistinguishable from each other except at high densities in Figure 4(b)) and agree well with our data in the lower density fluid region. In the literature, there are several other equations of state that are proposed as solutions to the Percus-Yevick equation which are slightly more accurate than the Carnahan-Starling equation. Examples of these include the Kolafa equation [35] and the Malijevsky and Veverka equation of state [36]. The Malijevsky and Veverka equation, for instance, uses a combination of the analytical solution of the Percus-Yevick equation and a Pade approximation of the rescaled virial series using the first seven virial coefficients to improve the convergence of the virial expansion. When we plotted the Kolafa and Malijevsky and Veverka equations of state we found that these solutions were very close to the Carnahan-Starling equation of state and gave no significant improvement in agreement with our data.

The close agreement between the virial/Carnahan-Starling result and our data is surprising. These theoretical results are based on the assumption that the grains are in a thermal equilibrium which would be characterized by a Gaussian distribution of velocities. In contrast to a conservative hard sphere fluid, a dissipative granular fluid does not form a Gaussian velocity distribution. Experiments [37, 38], theory [39–41] and simulations [8] have shown that in a granular fluid, the distribution of velocity fluctuations is not Gaussian. At low  $v_x$ , the  $v_x$ distribution fits a Gaussian but has stretched exponential tails. These tails gradually fill the whole distribution such that the entire distribution can be well fit with a 1.5 power law instead of the power-law exponent of 2 that would be expected for a Gaussian velocity distribution [8]. The lack of normal thermal equilibration is also particularly evident in the free-fall to fluid transition area

(the low density region in Fig. 4(b)). Here the  $P_{yy}$  data matches the Carnahan-Starling equation and the virial expansion, but  $P_{xx}$  and  $P_{zz}$  do not. This indicates that in this transition region, the fluid is not fully equilibrated in the x-x and z-z directions. Thus we shouldn't expect that Eq. (23) and the coincident virial expansion can be directly applied to a granular fluid. However, surprisingly the Carnahan-Starling and the virial expansion work extremely well in the fluid region, matching our simulation data. A reason may be that even though in the velocity distribution the 1.5 power law exists in the tails, the distribution still remains Gaussian in the center. This implies that the pressure in the fluid and free-fall region is not too sensitive to the tail distribution.

It is also remarkable that there is no real signature of the different phases in the pressure. The ratio of  $P/(\rho T)$  diverges as close packing is approached but is still finite throughout the glassy region. As we shall see below, these phases are only distinct when we consider dynamic properties such as transport coefficients. This fits with the usual description of the glass transition being a dynamical transition. What is perhaps more interesting is that the free-fall to fluid transition must also be a dynamic transition if these phases are truly distinct. We will examine this in more detail in later sections.

An asymptotically matched expression that interpolates between the virial and the free-volume expression for the pressure can be found by taking the virial expansion up to and including  $B_5\phi^4$  and adding to it Eq. (18) and subtracting the Taylor series expansion of Eq. (18) taken about  $\phi = 0$  up to and including the  $\phi^4$  term:

$$\frac{P}{\rho T} = \left(1 + B_2 \phi + B_3 \phi^2 + B_4 \phi^3 + B_5 \phi^4\right) 
+ \left[1 - \left(\frac{\phi}{\phi_c}\right)^{1/3}\right]^{-1} - \sum_{n=0}^{n=12} \left(\frac{\phi}{\phi_c}\right)^{n/3}. (24)$$

This is shown in Fig. 4 as the solid red line that goes through the simulation data.

#### D. Collision frequency

Many of the constitutive relations derived in following sections, such as for the dissipation and energy flux, will involve a collision frequency (per unit volume). Thus, it seems appropriate to first establish closed relations for the collision frequency,  $f_c$  that are valid in the different regions. As we will show below, a closed relation for the collision frequency can be found from the expression 5 for the stress measured in the simulation and the fact that Eq.(24) expresses the pressure in the different regions in terms of the density and temperature.

We use the sign convention for the pressure tensor  $P_{\alpha\beta} = -\sigma_{\alpha\beta}$ . The virial can be defined from the stress

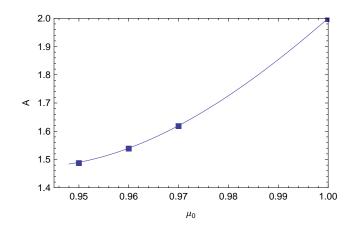

FIG. 5: Plot of the empirically determined parameter A in Eq. (30) for the glassy region of the chute from simulations with different asymptotic coefficients of restitution  $\mu_0$ . The line is just a guide for the eye.

as

$$V = -\frac{1}{3}Tr\left(\sigma_{\alpha\beta} - \langle \rho\left(v_{\alpha} - \langle v_{\alpha} \rangle\right)\left(v_{\beta} - \langle v_{\beta} \rangle\right)\rangle\right), \quad (25a)$$

$$\approx P - \rho T, \quad (25b)$$

where the pressure P is a function of the density  $\rho$  and granular temperature T as detailed in the previous section. The kinetic term in Eq. (25a),  $\langle \rho (v_{\alpha} - \langle v_{\alpha} \rangle) (v_{\beta} - \langle v_{\beta} \rangle) \rangle$ , is negligible in the glass but is significant in the fluid and free-fall regions.

Using Eq. (5) we also have the relation

$$V = \frac{1}{2} f_c \langle (1 + \mu)(\dot{\mathbf{r}}_1 - \dot{\mathbf{r}}_2) \cdot \mathbf{q} \rangle,$$
  
=  $f_c \langle 1 + \mu \rangle \langle v_n \rangle,$  (26)

where

$$(\dot{\mathbf{r}}_1 - \dot{\mathbf{r}}_2) \cdot \mathbf{q} = \mathbf{v_n} \tag{27}$$

is simply the normal impact velocity between the colliding particles and the factor of 1/2 disappeared because it was due to the double counting in the average over collisions (which counts the momentum transferred from particle 1 to 2 and from particle 2 to 1 in) and this is not present in the second line.

By combining Eqs. (25a) and (26) we have

$$f_c = \frac{3V}{\langle 1 + \mu(v_n) \rangle \langle v_n \rangle},\tag{28}$$

 $\mu(v_n)$  is the velocity-dependent coefficient of restitution given by Eq. (2).

During a collision the sign of  $v_n$  is fixed and  $v_n$  is always positive, as can be readily seen from Eq. (27). In Ref. [8], we showed that  $v_n^2$  traces the velocity fluctuations  $\delta v_\alpha^2$ . Thus we expect  $\langle v_n \rangle$  to be related to  $\langle |\delta v_\alpha| \rangle$ ,

$$\langle |\delta v_{\alpha}| \rangle = \sqrt{\frac{2}{\pi}} \langle \delta v_{\alpha}^2 \rangle^{1/2},$$
 (29)

if  $\delta v_{\alpha}$  is distributed in a Gaussian. This is nearly true in the liquid and free-fall regions. However,  $\delta v_{\alpha}$  is not strictly distributed in a Gaussian distribution in the glassy region. If the particles are moving statistically independently

$$\langle v_n \rangle = \sqrt{\frac{2}{\pi}} A T^{1/2}, \tag{30}$$

where A=2 in the liquid and free-fall regions. In the glassy region  $P(\delta v)$  is not Gaussian [8] and the particles are not moving or colliding independently [8, 18]. So  $\langle v_n \rangle_{\text{collisions}} \neq \langle \delta v \rangle_{\text{particles}}$ . Thus in the glass, A<2 and a value for A has to be determined empirically. For an asymptotic coefficient of restitution of  $\mu_0=0.97$ , we found A=1.62 in the glass. Figure 5 shows a plot of A in the glassy region for three different coefficients of restitution. As the simulation becomes more elastic, that is as  $\mu_0 \to 1$ ,  $A \to 2$ .

We also calculated A in the glassy region for simulations with different sieve probabilities, hence for different flow rates with the same asymptotic coefficient of restitution, and found that A did not vary with the flow rate in the glassy region.

Upon combining, Eqs. (2), (28), and (29), we finally arrive at closed expression for the collision frequency  $f_c$ ,

$$f_c = \frac{3V}{\left[2 - (1 - \mu_0) \left(\frac{\sqrt{\frac{2}{\pi}}AT^{1/2}}{v_0}\right)^{0.7}\right] \sqrt{\frac{2}{\pi}}AT^{1/2}}, \quad (31)$$

with A as defined for the different regions in the paragraph above. We have used the fact that in the glass the normal velocity,  $v_n$ , is less than the cutoff velocity  $v_0 = \sqrt{2ga}$  [23]. Fig. 6 shows that the collision frequency as calculated using Eq. (31), and the collision frequencies obtained from the simulation agree nicely. To use this expression in one of the continuum relations, the virial V would need to be calculated using Eq.(25b) and (24) which give V in terms of density and temperature.

#### E. Conservation equations in free-fall region

In this section, we will examine properties in the free-fall region which we can solve for analytically. In the free-fall region, the stresses are very small, and their gradients even smaller. As can be seen in the flat pressure profile in the free-fall region in the inset in Fig. 1(e), there is a small (mostly kinetic) stress contribution. This allows us to greatly simplify the above equations and solve for the density, velocity and energy in the free-fall region. As described in Ref. [8], the fluid region starts as a boundary layer in the free-fall region which gradually grows to dominate the flow. As such, what we describe in this section just applies to the plug-like flow in the central (away from the walls) portion of the channel. In this plug-like flow region, velocity gradients in the x-direction are negligible (e.g. see Fig. 3(b) in Ref. [8]), as are shear stresses

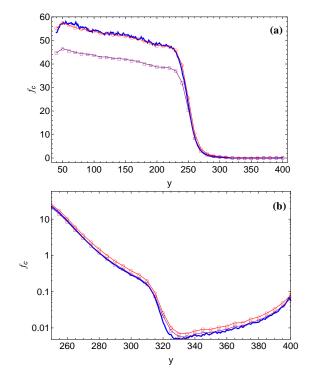

FIG. 6: Plot of the collision frequency per unit volume as calculated using Eq. (31) using A=1.62 (red line with o's), as calculated using Eq. (31) using A=2 (purple line with  $\square$ 's), and the simulation values for the collision frequency (blue solid line) versus the height y of the chute in (a) the entire chute and (b) in the fluid region (semi-logarithmic). Measurements are taken in the center of the chute using a simulation with an asymptotic coefficient of restitution  $\mu_0=0.97$ . (color online). Data is averaged over depth (32a) in z and over 800 time units.

 $\sigma_{xy}$ . Due to the periodic boundary conditions in the z-direction physical properties are translational invariant, on average, along z. Our system is in a steady state so we can also assume that the partial derivative with respect to time in Eq.(3), (4), and (6) are negligible.

With these assumptions in the free-fall region, the Continuity Eq. (3) translates to:

$$\partial_{u}\left(\rho v_{u}\right) = 0. \tag{32}$$

and the y component of the Navier-Stokes Eq. (4) translates to

$$\partial_y \left( \rho v_y^2 \right) = \partial_y \sigma_{yy} + \rho g. \tag{33}$$

There is a very small kinetic contribution to the stress as can be seen in the inset in Fig. 1(e):

$$\sigma_{yy} = -\rho \delta v_y^2. \tag{34}$$

However this kinetic stress contribution in the free-fall region is nearly constant (except close to the inlet) as can be seen by the horizontal profile in the inset in Fig. 1(e), and thus

$$\partial_y \sigma_{yy} = -\partial_y \rho \delta v_y^2 \approx 0. \tag{35}$$

We can then solve for the density and velocity in the free-fall region using Eqs. (32) and (33) and one data point in the bulk interior of the free-fall region at a height  $y_0$ , at mid-width (mid x-direction) and mid-depth (mid z-direction) in the chute. The reason we use an interior point as opposed to a boundary value, say at the top of the chute is because the assumption of  $\sigma_{yy}$  being constant is most true once the grains have moved a finite distance into the chute. This is not strictly a required assumption to solve the equations, but it is required if we wish to solve without consideration of the energy equation.

Thus solving Eqs. (32) and (33), gives us the solution

$$\rho = c/v_y, \tag{36}$$

$$v_y \approx -\sqrt{2gy + k_1},\tag{37}$$

where the constants are

$$k_1 = v_{y_0}^2 - 2gy_0, (38)$$

$$c = \rho_{y_0} v_{y_0}, (39)$$

$$c = \rho_{y_0} v_{y_0}, \tag{39}$$

where  $\rho_{y_0}$  and  $v_{y_0}$  are from any single point in the interior of the free-fall region as described in the previous paragraph. Eqs. (37) and (36) are plotted as dashed lines in the free-fall region in Fig. 1(b) and (c). The agreement between the analytical results and the simulation in the free-fall region is remarkably good. Not surprisingly, there is some deviation at the very top of the chute where the approximation that  $\sigma_{yy} \approx constant$  breaks down. As we noted above, in the free fall region the stress is almost entirely from the kinetic terms so that  $\sigma_{yy} = -\rho \delta v_y^2$  so to improve our analytic solution we must examine the energy equation (to obtain a better solution for  $\delta v_u^2$ ).

It is clear however, that to solve these equations analytically (or numerically without input from the simulation) that constitutive relations giving I and  $F_c$  are needed. These will be presented in section II G.

## Shear-Stress Constitutive Relations: Models of Viscosity

In references [8] and [18], it was demonstrated that the velocity profile of particles in the fluid region was parabolic (Poiseuille flow), but as one approached the glassy region a plug type profile emerged. The development of this plug profile in the y-velocity was clearly correlated with the center region solidifying into a glass. As the particles travel down the chute, they are slowed by the drag force at the walls supporting the weight of this glassy region via a shear stress. This gives a pluglike profile. We cannot overemphasize the important role that the shear stress has on the y-velocity profiles for particles traveling from the fluid to a glassy region. The stresses were shown to be crucial in providing the weight balance that we discussed in section IIB. In this section, we will discuss constitutive relations for the shear stress in the fluid and glassy regions of our granular system.

Most works based on kinetic theory assume a fluid-like constitutive relation for the shear stress in the system

$$\sigma_{xy} = \eta \partial_x v_y, \tag{40}$$

where  $\sigma_{xy}$  is the shear stress,  $\eta$  is the effective viscosity and  $\partial_x v_y$  is the shear rate. The difficulty with such descriptions is that the viscosity  $\eta$  is strongly dependent on things like the granular temperature which varies considerably in space in many granular systems.

This complexity can be seen in Fig. 7(a) which plots the shear stress,  $\sigma_{xy}$ , vs. the shear rate  $\partial_x v_y$  in the granular fluid region for different heights. Here, it was important to use a slow (p = 90%) system with a high enough asymptotic coefficient of restitution  $\mu_0 = 0.95$  in order to achieve a true fluid region of study. The temperature in this region is fairly uniform in width x but changes dramatically in height y (see Figs. 5 and 6 in reference [8]). We plotted the shear stress  $\sigma_{xy}$  versus the shear rate  $\partial_x v_y$  for different heights, hence at different temperatures for these different heights, as shown in Fig. 7(a). Fig. 7(a) does display the linear relation of Eq. (40). To calculate the viscosity  $\eta$ , we then measured the slopes of  $\sigma_{xy}$  versus  $\partial_x v_y$  at these different heights, and plotted these viscosity values versus the granular temperature Tat these heights. We obtained a power-law relationship between the viscosity and the granular temperature along heights in the fluid region as shown in Fig. 7(b).

$$\eta \sim T^{-4/3}.$$
(41)

Equation (41) for the fluid region seems surprising. If you recall, in section IIC, particularly by looking at Fig. 4, we were able to successfully match the pressure in the fluid region from our simulation to the pressure equation of state obtained from a virial expansion. Thus it would be logical that one should expect our fluid to behave as a hard sphere gas whose viscosity as given from any standard textbook [42] would be:

$$\eta = \frac{5}{64} \frac{1}{a^2} \sqrt{\frac{mk_B T}{\pi}},\tag{42}$$

where a is the particle radius, m its mass,  $k_B$  is Boltzmann's constant and T is the absolute temperature. One can see from Eq. (42), for a hard sphere gas, the viscosity  $\eta \sim T^{1/2}$ . Thus one would expect the viscosity to increase with temperature, but from Eq. (41) and the corresponding Fig. 7(b), the viscosity actually decreases with increasing temperature. This is not how a gas behaves. This behavior is often associated with a liquid whose viscosity grows larger as the temperature goes down as you approach the solid state. The viscosity in a liquid typically has an exponential relation that is found in standard textbooks [42]

$$\eta = \eta_0 e^{E_{a,\eta}/RT},\tag{43}$$

which as in our simulation data, does decrease with increasing temperature. In Eq. (43),  $E_{a,\eta}$  is the molar activation energy. The fact that we observe a power relation given by Eq. (41), and not the exponential relation given by Eq. (43), indicates that our granular fluid is not a truly equilibrated fluid. The data in Fig. 7(b), however, when plotted on a semi-logarithmic scale (Fig. 7(c)), seems to be approaching a straight line at higher temperatures (near the top of the fluid region), but not the 1/T suggested by Eq.(43).

Numerous experiments have measured velocities and forces in sheared granular matter [1, 43–45] confining granular matter in a Couette cell between a stationary outer cylinder and a rotating inner cylinder. These experiments are typically shearing a very dense granular state like our glass. In Ref. [46], the authors looked at the relationship between the square root of the granular temperature and shear rate that was observed in the glassy region of granular particles in a Couette cell. Our granular particles are in a shear flow traveling down the chute. The shear zones near the walls in the glassy state of our simulation should be comparable to these experiments.

Following the analysis given in reference [46], using  $\sigma_{xy} = \eta \dot{\gamma}$  with  $\dot{\gamma} = \partial_x v_y$  being the shear rate and  $\eta$  the viscosity, an expression was made for the viscosity to scale with the collision frequency,

$$\eta = \eta_0 P / \left( \rho_c d^2 T^{1/2} \right), \tag{44}$$

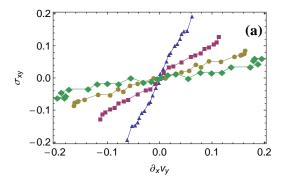

where d is the particle diameter,  $\eta_0$  is a dimensionless number, and  $\rho \sim \rho_c$  the close-packed density has been assumed, so that

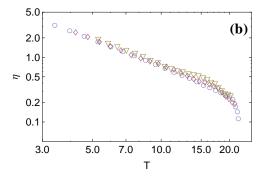

$$T^{1/2} = \eta_0 P / \left( \rho_c d^2 \sigma_{xy} \right) \dot{\gamma}. \tag{45}$$

However, this analysis can be taken further. If the pressure given in Eq. (44) followed the scaling  $P \sim \rho T$ , this would give the same scaling  $\eta \sim T^{1/2}$  as Eq. (42) for a hard sphere gas. This extension was not done in Ref. [46]. The analysis that was provided by the authors in Ref. [46], resulting in Eq. (45), gives  $\dot{\gamma} = \partial_x v_y \sim T^{1/2}$ . Their analysis did not lead to agreement with their experiment. Experimentally, they observed the following power-law with

$$T^{1/2} \sim |\partial_x v_y|^{0.4}$$
 (46)

A log-log plot of the square root of the granular temperature vs shear rate as measured from our simulation on one side of the chute (from middle to the wall) in the glassy region is shown in Fig. 8(a). We plotted this for a series of systems with different probabilities of sieve reflection, p and different asymptotic coefficients of restitution  $\mu_0$ . On a log-log plot the top curve in Fig. 8(a) vaguely resembles a power-law exponent of 0.4 as in experiment [46] for a fast system (p = 1%,  $\mu_0 = 0.9$ ), and as shown by the superimposed bottom curves in Fig. 8(a), for the slower systems (p = 90%) with  $\mu_0 = 0.9$ , 0.95, 0.96 and 0.97, the slope is 0.2, although this isn't as clear a linear regime on a log-log plot of the square root of the granular temperature (velocity fluctuations) vs. the shear rate

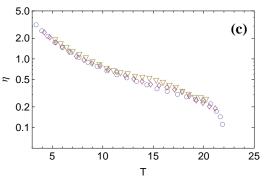

FIG. 7: (a) Shear stress  $\sigma_{xy}$  versus shear rate  $\partial_x v_y$  in the fluid region for a slow flow (probability of reflection at the bottom sieve of p=90%,  $\mu_0=0.95$ ). The symbols indicate data at different heights in the fluid region ( $\blacktriangle$ 's at y=277,  $\blacksquare$ 's at y=283,  $\bullet$ 's at y=289 and  $\bullet$ 's at 295), (b) Log-log plot of viscosity and (c) semilogarithmic plot of viscosity in the fluid region (slope of data in (a)). The symbols indicate different asymptotic coefficients of restitution,  $\mu_0$  (with o's using  $\mu_0=0.95$  and p=90%, o's using  $\mu_0=0.96$  and p=90%, and  $\nabla$ 's using  $\mu_0=0.97$  and p=90%). Systems with the higher asymptotic coefficients of restitution of  $\mu_0=0.95$ , 0.96 and 0.97 achieve a true fluid region and have a consistent power-law of  $-\frac{4}{3}$ .)

for the slower systems as for the faster system. Thus the power law exponent of 0.4 that was reported in the experimental paper [46] is not universal.

Eq. (46) indirectly assumes that the viscosity in the sheared glass is a function of the granular temperature. Using the relation  $\sigma_{xy} = \eta \partial_x v_y$ , we can plot the viscos-

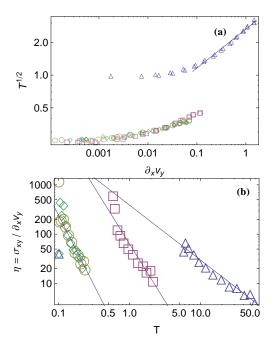

FIG. 8: (a) Log-Log plot of square root of temperature versus shear rate. A system with a fast flow (probability of reflection at the bottom sieve of p=1%,  $\triangle$  and  $\mu_0=0.9$ ) yields a region with the experimental power law exponent of 0.4 (line), while slow systems (probability of reflection at the bottom sieve of p=90% with  $\mu_0=0.9$   $\square$ ,  $\mu_0=0.95$   $\circ$ ,  $\mu_0=0.96$   $\diamond$ , and  $\mu_0=0.97$   $\triangledown$ ) have a pseudo-power-law with exponent 0.2. (b) Log-log plot of effective shear viscosity  $\eta=\sigma_{xy}/\partial_x v_y$  versus temperature T in the glassy transition region for a fast flow  $(\triangle)$  and slower flows (symbols same as in (a)). The solid lines have slopes of -1.1 for the fast system, -2.3 for the slow system with  $\mu_0=0.9$ , and -2.8 for the slow systems with  $\mu_0=0.95$ , 0.96 and 0.97.

ity,  $\eta$  as  $\sigma_{xy}/\partial_x v_y$ , versus the granular temperature, T, in the glassy region for both a slow (p=90%) system yielding a power law of 1.1 and a fast (p=1%) system yielding a power law of 2.3. This is shown as a log-log plot in Fig. 8(b). Clearly, the power-law exponent is not universal here.

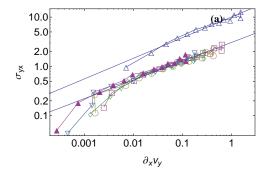

We can however obtain a universal power law in the sheared glass by plotting the shear stress,  $\sigma_{xy}$ , vs. the shear rate,  $\partial_x v_y$ , on a log-log plot as shown in Fig. 9. We found a universal power law of 0.4 for both slow and fast systems on one side of the chute:

$$\sigma_{xy} = B|\partial_x v_y|^{0.4},\tag{47}$$

with B a constant. This is equivalent to obtaining a universal power law by further plotting (not shown) the viscosity,  $\eta$  on one side of the chute in the glassy region versus the shear rate,  $\dot{\gamma} = \partial_x v_y$  and witness a universal power law of approximately -0.6:

$$\eta = B|\partial_x v_y|^{-0.6} \tag{48}$$

The universal power-law between the shear stress and

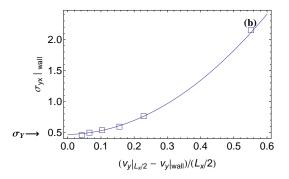

FIG. 9: (a) Log-log plot of shear stress  $\sigma_{yx}$  versus shear rate  $\partial_x v_y$  in the glassy region for various flow rates (probability of reflection at the bottom sieve of p=0.01 as  $\triangle$ 's, p=0.1 as  $\square$ 's, p=0.25 as  $\circ$ 's, p=0.5 as  $\triangle$ 's, p=0.75 as  $\nabla$ 's, and p=0.9 as  $\blacktriangle$ 's), all with an asymptotic coefficient of restitution of  $\mu_0 = 0.9$ . The solid straight lines have slopes of 0.41 for the upper line and 0.38 for the lower line. (b) Plot of shear stress  $\sigma_{yx}$  at the wall versus the y velocity at the center at  $L_x/2$  minus the y velocity at the wall, scaled by  $L_x/2$ . The yield stress  $\sigma_Y$  is indicated by the arrow. Data is from a  $32 \times 32 \times 250$  column.

strain rate given by Eq. (47) and shown in Fig. 9(a) makes one wonder whether we have a true glassy region. Consider in Fig. 9(a) a typical region where a particle of radius a undergoes a strain rate  $\partial_x v_y$  of 0.01. In this region,  $v_y \sim 1$  so using the relation

$$\partial_x v_y = \frac{\Delta v}{a},\tag{49}$$

we can say that it takes 100 time units for one grain to pass another. However, using the typical size and velocities from Fig. 1 the time that a particle has in the glassy portion of the chute is

$$\frac{L_y}{v_y} \approx \frac{200}{1} = 200 \text{ time units.} \tag{50}$$

Thus, in our glassy region, it takes about the same amount of time for one grain to pass another as it takes for all the particles to traverse the entire chute. It is also clear from Fig 9(a) that Eq.(47) is not valid all the way into the interior (low strain-rate region) of the system and significant deviations occur below  $\sigma_{xy} \lesssim 0.4$ . Another significant caveat is that we have taken the strain

rate  $\partial_x v_y$  as the derivative of the *time* averaged velocity profile. While the time-averaged profile is smooth, an instantaneous velocity profile is much more discontinuous (so much so that one cannot meaningfully take a numerical derivative) suggesting more discrete fault-like slips occurring in the glass rather than the local rearrangements typical of a fluid.

If we look at the plot of shear stress at the wall (experimentally measurable shear stress) versus the scaled y velocity at the center minus the y velocity at the wall (experimentally observable strain rate) shown in Fig. 9(b), we do observe a finite shear stress when the scaled y velocity at the center minus the y velocity at the wall is zero. This indicates that our glassy region has a yield stress at this zero velocity as would be expected for a glassy region. Doing the same thing in the fluid region (not shown) shows a 0 intercept at small strain rates indicating the lack of a yield stress there. A constitutive relation for the static central portion of the glass is still needed as we have only really described the shear zones near the wall in this section. We will consider this in more detail in Section II H.

It is interesting to note that in no region do we observe the Bagnold scaling [1] of

$$\sigma_{xy} \sim (\partial_x v_y)^2.$$
 (51)

However, Bagnold did not measure the shear stress or strain rate locally but rather deduced them from the externally applied stress and strain in a Couette cell. This is more similar to our analysis in Fig. 9(b) which does exhibit this quadratic relationship. However, our simulation is more akin to Poiseuille flow rather than Couette flow so a direct comparison is not necessarily valid. However, it does raise the possibility that Bagnold scaling is, similar to the relationship between  $\delta v$  and v found by Menon and Durian [6, 8], not a local relationship but a statement about a more global force/energy balance. However, simulations in the Couette geometry would be needed to comment further on this aspect. Simulations using Hertzian contact types of interactions have seen regions of Bagnold scaling [47]. However, these simulations found that in the regions where Bagnold scaling was obverved transmission of stresses was dominated by contacts rather than collisions. It is possible that the addition of tangential dissipation (i.e. friction) during a collision would be key to seeing Bagnold scaling but, if so, would not be consistent with Bagnolds original argument which was based on binary collisions.

## G. Energy equation

In section II A, the energy conservation during steady-state was expressed as

$$\partial_t (E) + \partial_\alpha (F_\alpha) = I + \rho g \cdot \mathbf{v}.$$
 (52)

In this section, we will examine the energy flux  $\mathbf{F}$  and the dissipation I and relate them to the density and temper-

ature. We assume that the time derivative,  $\partial_t E$  is zero because we are in steady state. We will focus first on the energy flux  $\mathbf{F}$ .

As stated in [28], there is a difference between the "energy flux",  $\mathbf{F}$ , and the "heat flux",  $\mathbf{Q}$ . The heat flux,  $\mathbf{Q}$  is the uncorrelated part of the energy flux, and can be found using

$$\mathbf{Q} = \mathbf{F_c} + (\sigma \cdot \mathbf{v}), \tag{53}$$

where  $\mathbf{F_c}$  is the collision energy flux defined by Eq. (10) and  $\sigma$  is the stress tensor defined by Eq. (5). In Eq. (53),  $\sigma \cdot \mathbf{v}$  represents the *coherent* transfer of energy (i.e. non-dissipative) during collisions.

Fourier's law suggests that the heat flux across the chute,  $Q_x$ , can be expressed as proportional to the gradient of the granular temperature, T, by the relation

$$Q_x = -\kappa \partial_x T \tag{54}$$

where  $\kappa$  is the thermal conductivity. In our *fluid* region, we plotted the heat flux,  $Q_x$  versus the gradient of the granular temperature,  $\partial_x T$ , across the width (x direction) of the chute. This is shown in Fig. 10(a) for a slow system using a probability of reflection at the bottom sieve of p = 90% and an asymptotic coefficient of restitution of  $\mu_0 = 0.95$ . Systems with higher coefficients of restitution had the largest fluid regions. It was important here to choose a system with a high asymptotic coefficient of restitution in order to maintain a true fluid region. Otherwise with lower coefficients of restitution, we would have just a combination of fluid to glass and fluid to free-fall transition regions. As one can see for various heights in the fluid region, the data in Fig. 10(a) falls on straight lines. The negative slopes of these straight lines give the thermal conductivity

$$\kappa = -\frac{Q_x}{\partial_- T}. (55)$$

In Fig. 10, the thermal conductivity,  $\kappa$  was calculated as a linear fit and is shown on a semi-logarithmic plot versus the granular temperature at a range of heights in the fluid region for three slow systems (p=90%). Fig. 10 shows systems with different asymptotic coefficients of restitution of  $\mu_0=0.95$  shown as  $\Box$ 's, 0.96 shown as  $\circ$ 's and 0.97 shown as  $\nabla$ 's. Interestingly, all three systems consistently give an exponential fit in the fluid region of

$$\kappa = Ae^{-T/T_0},\tag{56}$$

where  $T_0 \sim 11$ , and A is a multiplicative constant.

We can contrast Eq. (56) to a thermal conduction expression for a hard sphere gas given in reference [42]

$$\kappa = \frac{25}{128} \frac{c_v}{a^2} \left(\frac{k_B T}{\pi m}\right)^{1/2},\tag{57}$$

where  $c_v$  is a specific heat and a is the particle radius. It does not really make sense for our granular gas to

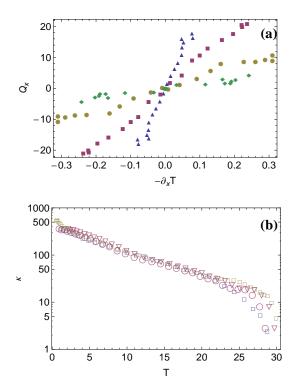

FIG. 10: (a) Heat flux  $Q_x$  versus granular temperature gradient,  $-\partial_x T$ , in the fluid region (probability of reflection at the bottom sieve of p=90%,  $\mu_0=0.97$ ). The symbols indicate data at different heights in the fluid region ( $\blacktriangle$ 's at y=274,  $\blacksquare$ 's at y=284,  $\bullet$ 's at y=294 and  $\bullet$ 's at y=304), (b) Semi-logarithmic plot of thermal conductivity,  $\kappa=-Q_x/\partial_x T$  versus the granular temperature, T, in the fluid region for systems with a probability of reflection at the bottom sieve of p=90%. The symbols indicate different asymptotic coefficients of restitution,  $\mu_0$ . (with  $\Box$ 's using  $\mu_0=0.95$ ,  $\circ$ 's using  $\mu_0=0.96$ , and  $\nabla$ 's using  $\mu_0=0.97$ ). All three systems give an exponential fit of  $\kappa\sim e^{-T/T_0}$  with  $T_0\sim 11$ .

have a specific heat as we potentially could argue for an infinite specific heat for our dissipative simulation (any energy added to the system is eventually dissipated). From the equation for the thermal conductivity of a hard sphere gas given by Eq. (57), one gets the impression that  $\kappa \sim T^{1/2}$  and thus that the thermal conductivity should increase with temperature. The thermal conductivity for our granular fluid does not increase with temperature, but exponentially decays with increasing temperature as given by Eq.(56). Thus once again our granular fluid cannot be considered as a hard sphere gas. Our fluid behaves as a liquid: as the temperature goes down, the thermal conductivity increases as you would expect in a material that approaches a solid state as our glassy region.

Next, we examine the thermal conductivity in the glassy region. The heat flux,  $Q_x$  is plotted in the glassy region in Fig. 11 across the width (x direction) of the

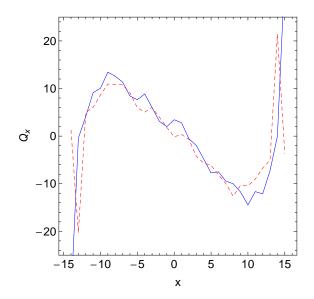

FIG. 11: Log-log plot of heat flux  $Q_x = -\kappa \partial_x 3T$  vs. width x for a 15% polydisperse 3D simulation for a glassy region at y=200 where  $\kappa=4/3\pi a^3 \rho f_c$ . The solid line is  $Q_x=F_{cx}+\sigma_{xy}v_y$ , and the dashed line is  $Q_x=-4/3\pi a^3 \rho f_c \partial_x 3T$ .

chute. As shown in Fig. 11, in the glassy region

$$\kappa = 3\phi f_c = \frac{4}{3}\pi a^3 \rho 3 f_c, \tag{58}$$

(the density times the collision frequency). Eq. (58) is the same equation as in reference [28] found in 2D where we measured density there as a volume fraction [48]. As the collision frequency is known in terms of the density and temperature (section II D) this gives a closed expression for the conductivity in the glass.

The remaining term for which we need a constitutive relation is the dissipation, I. Since the coefficient of restitution  $\mu$ , is highly correlated with the impact velocity  $v_n$ , we cannot simply factor the terms in Eq.(11),  $-\frac{1}{4}\langle(1-\mu^2)v_n^2\rangle$  as  $-\frac{1}{4}\langle1-\mu^2\rangle\langle v_n^2\rangle$  (we could factor out  $(1+\mu)$  in previous expressions, such as for the collision frequency, because the relative change in  $(1+\mu)$  for different  $v_n$  is small whereas the relative change in  $(1-\mu^2)$  for different  $v_n$  is large). We outline below two different constitutive relations for I based on different assumptions.

In the first case, we assume that dissipation is dominated by the high impact collisions. We consider a small proportion, say b, of the dissipation involves  $v_n$  being greater than the cutoff velocity  $v_0$  in our velocity-dependent coefficient of restitution Eq. (2), and a proportion 1-b of the dissipation involves  $v_n < v_0$ . Then we have

$$\langle \delta I \rangle = \langle -\frac{1}{4} (1 - \mu^2) v_n^2 \rangle$$

$$= b \langle -\frac{1}{4} (1 - \mu_0^2) v_n^2 \rangle_{v_n > v_0}$$

$$+ (1 - b) \langle -\frac{1}{4} (1 - \mu^2) v_n^2 \rangle_{v_n < v_0}.$$
(59)

Now, for  $v_n < v_0$ 

$$\langle -\frac{1}{4}(1-\mu^2)v_n^2 \rangle_{v_n < v_0} \approx 0,$$
 (60)

because  $\mu \approx 1$  and  $v_n$  is also small for these collisions. Similarly, the small value of  $v_n$  for collisions with  $v_n < v_0$  gives

$$\langle v_n^2 \rangle_{\mathbf{all}} = b \langle v_n^2 \rangle_{v_n > v_0} + (1 - b) \langle v_n^2 \rangle_{v_n < v_0},$$
  

$$\approx b \langle v_n^2 \rangle_{v_n > v_0}.$$
(61)

Putting it all together gives

$$\langle \delta I \rangle = \frac{1}{4} (1 - \mu_0^2) \langle v_n^2 \rangle. \tag{62}$$

This is the expression we expect to be correct if high velocity impacts dominate the dissipation.

However, most collisions occur with  $v_n < v_0$  (although these collisions are less dissipative so they may, or may not, impact the total dissipation I). If the coefficient of restitution formula for  $v_n < v_0$  is used directly and substituted into Eq. (2) and the average of the entire expression is evaluated one gets

$$\langle \delta I \rangle = \frac{1}{2} \frac{(1 - \mu_0)}{v_0^{0.7}} \langle v_n^{2.7} \rangle - \frac{(1 - \mu_0)^2}{4v_0^{1.4}} \langle v_n^{3.4} \rangle. \tag{63}$$

One can relate the averages of  $\langle v_n^{2,7} \rangle$  and  $\langle v_n^{3.4} \rangle$  to  $\langle v_n^2 \rangle$  similar to Eq.(29). The total dissipation can be found as

$$I = \langle \delta I \rangle f_c, \tag{64}$$

with  $f_c$  given in terms of density and temperature as described in Section II D.

Figure 12 shows, on a semi-logarithmic plot, the dissipation from the simulation plotted along with the constitutive Eqs. (62) and (63) (multiplied by the collision frequency). The constitutive equation given by Eq. (62) matches the dissipation from the simulation nicely in the liquid and glass regions, strongly supporting the argument that dissipation in these regions is completely dominated by the high impact velocity collisions. For the free-fall region the dissipation goes from Eq. (63) at the top to Eq. (62) at the fluid-free-fall transition. Thus, somewhat surprisingly the free-fall region is the only region where the dissipation is not dominated by the higher velocity collisions.

## H. Static Limit

We now examine the existence of a static limit to the glassy state of our system. The relationship between stress and strain rate in the glassy region, Eq. (47), is not that satisfying as one approaches the static limit because it is really a time-averaged response function. That is, as mentioned in Section IIF, for the low strain rates near the center of the chute it may take more time on

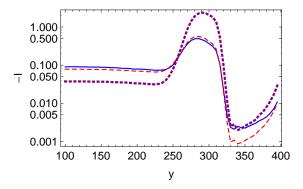

FIG. 12: Semi-logarithmic plot of the negative of the dissipation, -I, from the simulation as calculated from Eq. (11) (blue solid line), as calculated using Eq. (62) (red dashed line), and as calculated using Eq. (63) (purple dotted line).

average for one grain to pass another than it takes all particles to traverse the entire chute. As one approaches the static limit the time one would need to average over for this to be a useful consitutive relation becomes longer and longer. In this section we examine the stress in the glassy region in more detail and relate it to various other constitutive relations proposed for static granular materials. First we will demonstrate that there is a static limit to our equations for stress.

In the first step to simplifying the stress tensor, we write the 3D stress tensor given in Eq. (6) as [28]:

$$\sigma_{\alpha\beta} \approx -\langle \rho (v_{\alpha} - \langle v_{\alpha} \rangle) (v_{\beta} - \langle v_{\beta} \rangle) \rangle$$

$$- \frac{1}{2} f_{c} \langle (1 + \mu) (\mathbf{\dot{r}_{1}} - \mathbf{\dot{r}_{2}}) \cdot \mathbf{\hat{q}} \rangle \langle (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}) \rangle$$
(65)

In Eqs. (5) and (65) the sum is over collisions in a (long) time interval t and  $f_c$  is the collision frequency. In going from Eq. (5) to Eq. (65) we have assumed that we could separate the factor  $(1 + \mu)(\mathbf{\dot{r}_1} - \mathbf{\dot{r}_2}) \cdot \mathbf{\hat{q}}$  from the factors in the matrix  $\langle (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}) \rangle$  when computing averages (i.e. we have assumed that these factors are statistically independent). The validity of this assumption is shown in Fig. 13 which plots the stress components  $\sigma_{\alpha\beta}$  directly from Eq.(5) where the terms are unfactored, and  $R_{\alpha\beta} = \frac{1}{2} f_c \langle (1+\mu)(\mathbf{\dot{r}_1} - \mathbf{\dot{r}_2}) \cdot \mathbf{\hat{q}} \rangle \times \langle (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}) \rangle$  versus the width x or height y. As advertised, the virial term factors.

In a granular glass the kinetic term,  $\langle \rho v_{\alpha} v_{\beta} \rangle$  is negligible. As shown in Fig. 14(a), the factor  $f_c \langle (1+\mu)(\dot{\mathbf{r}}_1 - \dot{\mathbf{r}}_2) \cdot \hat{\mathbf{q}} \rangle$  in front of the matrix changes dramatically in the fluid region but in comparison appears to be nearly constant in the glassy region. Fig. 14(b) plots the factor  $f_c \langle (1+\mu)(\dot{\mathbf{r}}_1 - \dot{\mathbf{r}}_2) \cdot \hat{\mathbf{q}} \rangle$  for different sieve reflection probabilities and shows that for slower systems, this factor approaches a a constant. Hence the structure of the stress tensor in the glass comes almost entirely from the collision directions (i.e. the  $\langle (\hat{\mathbf{q}} \cdot \hat{\mathbf{e}}_{\alpha}) (\hat{\mathbf{q}} \cdot \hat{\mathbf{e}}_{\beta}) \rangle$  terms in Eq. (65)). This is very reminiscent of models describing static granular materials based on force chains.

For our particular case, we do not actually need a further relation for the shear stress to solve the stress bal-

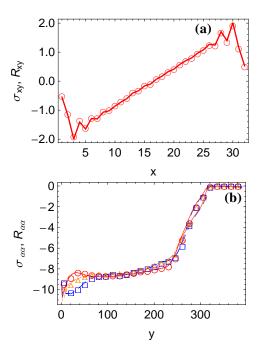

FIG. 13: Shear stress  $\sigma_{xy}$  (solid line) and  $R_{xy}$  (circles)(right hand side of Eq. (65), the shear stress factorized into the collision directions,  $\langle (\hat{\mathbf{q}} \cdot \hat{\mathbf{x}}) (\hat{\mathbf{q}} \cdot \hat{\mathbf{y}}) \rangle$  and the constant  $-\frac{1}{2} f_c \langle (1 + \mu)(\dot{\mathbf{r}}_1 - \dot{\mathbf{r}}_2) \cdot \hat{\mathbf{q}} \rangle$ ) versus x in (a) the glassy region at a height, y = 100. (b) Plot of the diagonal stress,  $\sigma_{\alpha\alpha}$  with its kinetic term (lower curves) and without its kinetic term (upper curves), and factor  $R_{\alpha\alpha}$  versus height y. ( $\sigma_{xx}$  is the solid line,  $\sigma_{yy}$  is the dashed line, and  $\sigma_{zz}$  is the dot-dashed line,  $R_{xx}$  is circles,  $R_{yy}$  is squares, and  $R_{zz}$  is triangles). Data is for a 400-height column using an asymptotic coefficient of restitution  $\mu_0$  of 0.97 and a probability of reflection, p = 0.9.

ance Eq. (12). As  $\partial_y \sigma_{yy} \approx 0$  in the glassy state, it is clear that  $\sigma_{xy} \approx \rho gx + constant$ . Making use of symmetry about the center (x=16) of the chute, it follows that the constant should be  $-\rho g16$ . However, this is really just a statement about stress balance in the system and requires the a-priori assumption of the shear stress supporting the weight. In order to compare to other constitutive relations suggested for static granular materials it is worthwhile to decompose the stress/pressure tensor into its eigenvalues  $\Lambda_i$  and eigenvectors  $\hat{n}$ ,  $\hat{m}$ , and  $\hat{l}$ :

$$p_{\alpha\beta} = -\sigma_{\alpha\beta} = \Lambda_1 n_{\alpha} n_{\beta} + \Lambda_2 m_{\alpha} m_{\beta} + \Lambda_3 l_{\alpha} l_{\beta}. \tag{66}$$

Note that the stress tensor is real, symmetric, and nonsingular so the eigenvectors are mutually orthogonal. The measured values of the eigenvalues and eigenvectors of our stress tensor are shown in Fig. 15. Note that the tensor nature of the stress is determined entirely by  $\langle (\hat{\mathbf{q}} \cdot \hat{\mathbf{e}}_{\alpha}) (\hat{\mathbf{q}} \cdot \hat{\mathbf{e}}_{\beta}) \rangle$  so eigenvectors tell us about the directions of the *collision chains* in our system (as  $\hat{\mathbf{q}}$  are the directions of the collisions) and these typically propagate through our particles at 45 degrees to the x/y axes as seen in Fig. 15: in the glassy region of our system these

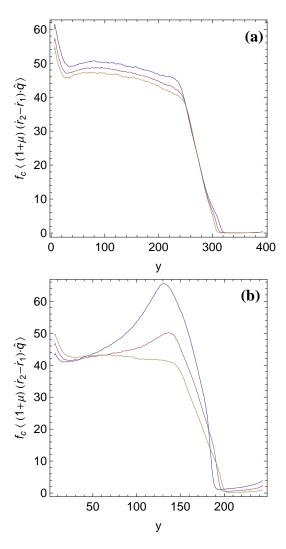

FIG. 14: (a) Plot of  $f_c\langle(1+\mu)(\dot{\mathbf{r}}_1-\dot{\mathbf{r}}_2)\cdot\hat{\mathbf{q}}\rangle$  vs. height y for a 400-height column. The lines from bottom to top represent data with asymptotic coefficients of restitution  $\mu_0$  of 0.95, 0.96 and 0.97, all with a sieve reflection probability, p=0.9. Data is averaged over the width (x direction). (b) Plot of  $f_c\langle(1+\mu)(\dot{\mathbf{r}}_1-\dot{\mathbf{r}}_2)\cdot\hat{\mathbf{q}}\rangle$  vs. height y for a 250-height column. The lines from top to bottom represent data with sieve reflection probabilities p of 0.25, 0.5 and 0.75, all with an asymptotic coefficient of restitution  $\mu_0=0.9$ .

"directors" can be expressed as

$$\hat{n} = \left(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0\right), \tag{67a}$$

$$\hat{m} = \left(-\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0\right), \tag{67b}$$

$$\hat{l} = (0, 0, 1).$$
 (67c)

This connection of the eigenvectors of the stress tensor with collision chains is very similar to models proposed for static sandpiles, such as the Fixed Principle Axes (FPA) models [14]. These early models suggested " $\hat{n}$ ,

 $\hat{n}$ ,  $\hat{l}$  (as) directors along three nonparallel populations of force chains; the  $\Lambda$ 's are compressive pressures acting along these. Body forces cause  $\Lambda_{1,2,3}$  to vary in space," [14], however  $\hat{n}$ ,  $\hat{m}$ ,  $\hat{l}$  are fixed and are not allowed to change in space, at least in some of these models. They must be determined from global symmetries and boundary conditions.

We can, however, solve for the eigenvalues and eigenvectors of the stress tensor independent of any particular model. Any stress tensor of the expected form,

$$\begin{pmatrix}
-p & \tau & 0 \\
\tau & -p & 0 \\
0 & 0 & -p
\end{pmatrix}$$
(68)

has the eigenvectors of Eq. (67). Using Eqs. (4) and (12) in the static limit, we have component-wise

$$\partial_x \sigma_{yx} + \partial_y \sigma_{yy} = -\rho g_y = \rho g, \tag{69a}$$

$$\partial_x \sigma_{xx} + \partial_y \sigma_{xy} = 0, \tag{69b}$$

$$\partial_z \sigma_{zz} = 0. ag{69c}$$

Using the known stress directors Eqs. (67) we can express the stress tensor in terms of its eigenvalues in our glassy region giving

$$\sigma_{xy} = \sigma_{yx} = -\Lambda_1 \frac{1}{2} + \Lambda_2 \frac{1}{2}, \qquad (70a)$$

$$\sigma_{yy} = -\Lambda_1 \frac{1}{2} - \Lambda_2 \frac{1}{2},\tag{70b}$$

$$\sigma_{xx} = -\Lambda_1 \frac{1}{2} - \Lambda_2 \frac{1}{2}, \tag{70c}$$

$$\sigma_{zz} = -\Lambda_3. \tag{70d}$$

Finally, combining Eqs. (69) and (70) we arrive at

$$(\partial_x \Lambda_1 - \partial_x \Lambda_2) \frac{1}{2} + \frac{1}{2} (\partial_y \Lambda_1 + \partial_y \Lambda_2) = -\rho g, \quad (71a)$$

$$(\partial_x \Lambda_1 + \partial_x \Lambda_2) \frac{1}{2} + \frac{1}{2} (\partial_y \Lambda_1 - \partial_y \Lambda_2) = 0,$$
 (71b)

$$\partial_z \Lambda_3 = 0. \tag{71c}$$

The general solution to Eqs. (71) is

$$\Lambda_1 = -\rho gx + C_1(y - x)$$

$$\Lambda_2 = \rho gx + C_2(x + y)$$

$$\Lambda_3 = C_3(x, y)$$
(72)

where  $C_1$ ,  $C_2$ , and  $C_3$  are arbitrary functions of the arguments indicated. Thus, we see that just specifying the eigenvectors, as in FPA models, still does not leave us with a solution without arbitrary functions. Even the boundary conditions do not uniquely specify a solution as different solutions are possible in different regions. If we invoke symmetry properties at mid-width (at x=16) then

$$\Lambda_1 = -(\rho g - c)(x - 16) - cy + p, 
\Lambda_2 = (\rho g - c)(x - 16) - cy + p, 
\Lambda_3 = -cy + p,$$
(73)

is the most general solution if we restrict ourselves to linear functions for the  $C_i$ . Taking  $c \approx 0$  gives a good match to the observed eigenvalue solutions in the glassy region plotted as thick transparent lines in the top left plot of Fig. 15. These lines reasonably match our simulation data. Taking  $c = \rho g$  gives the hydrostatic case (isotropic everywhere, weight supported by a pressure gradient) which would result in our stress tensor having no shear stresses, a situation much closer to that observed in the fluid where shear stresses are much smaller than in the glassy region. If the fluid were perfectly isotropic we could get linear combinations of eigenvectors for degenerate eigenvalues. However, this isotropy is broken in the y-direction and so the eigenvectors in the fluid region are not exactly those of Eq(67) and the near degenercy leads to more noise, especially near the boundaries. As we know the glassy region is supported by shear stress and the liquid by a pressure gradient we can distinguish limiting cases in our system but cannot determine c apriori.

A more recently proposed constitutive law for dense granular flows [49] is that the effective viscosity

$$\eta = \chi P / \sqrt{0.5 \partial_{\alpha} v_{\beta} \partial_{\alpha} v_{\beta}}, \tag{74}$$

where  $\chi$  is an internal friction coefficient. In our case, this implies that

$$\sigma_{xy} = \sqrt{2}\chi P. \tag{75}$$

In the dense glassy region of our system, we have established that the thermal contribution to the stress tensor is neglible so that Eq. (65) becomes

$$\sigma_{\alpha\beta} \approx -\frac{1}{2} f_c \langle (1+\mu)(\mathbf{\dot{r}_1} - \mathbf{\dot{r}_2}) \cdot \mathbf{\hat{q}} \rangle \langle (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}) \rangle$$

$$= \langle (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\alpha}) (\mathbf{\hat{q}} \cdot \mathbf{\hat{e}}_{\beta}) \rangle P, \qquad (76)$$

where we have used the relation  $P = -\frac{1}{3}Tr\sigma_{\alpha\beta}$  and that  $Tr\langle(\hat{\mathbf{q}}\cdot\hat{\mathbf{e}}_{\alpha})(\hat{\mathbf{q}}\cdot\hat{\mathbf{e}}_{\beta})\rangle \equiv 1$  as  $\hat{\mathbf{q}}$  is a unit vector. Thus we see that Eq.(75) appears to comes out naturally as all components of the stress tensor are proportional to P, as long as the thermal contribution to the stress is neglible. For simple shear flows, Ref. [49] also found that the relation

$$\chi = \chi_s + \chi_2(\dot{\gamma}, P), \tag{77}$$

worked well, where the first term  $\chi_s$  is a constant and the second term is a function of shear rate and pressure and vanishes in the limit that  $\gamma \to 0$ . While such a relation may work in a couette-like (simple shear) geometry where the shear stress is constant even in regions where the strain rate vanishes, such a relation cannot work in a chute or Poiseuille-like geometry unless  $\chi_s = 0$ . This is due to the fact that a fairly generic feature of chute-flow is that at the center of the chute we have  $\dot{\gamma} = 0$  and  $\sigma_{xy} = 0$  but P is nonzero. Setting  $\chi_s$  to zero for the chute-like flow would then likely cause the relation to fail for the couette-like geometry. It seems likely that

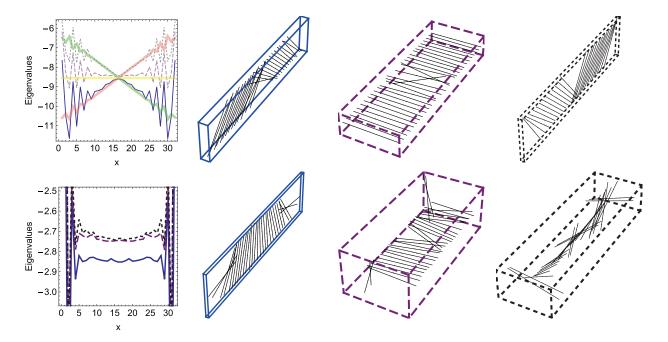

FIG. 15: Plot of the eigenvalues (compressive stresses) and corresponding directions of the stress tensor along width of column in (Top) the glassy region at y=138, and (Bottom) in the fluid region at y=294 for a 400-height column using an asymptotic coefficient of restitution  $\mu_0$  of 0.97. In both (Top) and (Bottom), the eigenvalues are associated alongside with the eigenvector directions by the style of the lines. That is, the line style of the eigenvalues (shown as solid, dashed or dotted lines) are matched with the line style of the box (shown as a solid, dashed or dotted lined box) surrounding the particular eigenvector directions. The analytical solution for the eigenvalues given by Eq. (73) with c=0 are plotted as thick lines with  $\Lambda_1$  drawn in pink,  $\Lambda_2$  in green and  $\Lambda_3$  in yellow. (Color online)

the static limit is more complex than that implied by Eq.(75) with constant  $\chi = \chi_s$ . However, it is still worth examining the approach to the static limit described by  $\chi_2$ .

The functional form for  $\chi_2$  suggested by Ref. [49] is not consistent with our observations in Section II F, in particular Eq. (47) and Figure 9(a). However, Peyneau and Roux [27] found that their simulations of homogeneously sheared frictionless grains was fit well by the form

$$\sigma_{xy} = \left[ \chi_s + c(\partial_x v_y / \sqrt{P})^{\alpha} \right] P \tag{78}$$

with c a constant and  $\alpha \approx 0.39$ . As the pressure is nearly constant in the glass, this is in excellent agreement with Eq.(47), including nearly identical exponents, as long as one takes  $\chi_s = 0$  for Poiseuille flow. Peyneau and Roux [27] also found a shear induced dilation that they fit to

$$\phi^{-1} = \phi_c^{-1} + D(\partial_x v_y / \sqrt{P})^{\nu} \tag{79}$$

with D a constant and  $\nu \approx 0.41$ . We find a similar dilation in the glass going from the center of the chute (where the shear rate is zero) to the wall, as shown in Fig. 16. However, we find an exponent of  $\nu \approx 0.6$ . Considering Peyneau and Roux were using a homogeneous shearing and a Hertzian contact model whereas we have the additional layering of grains in the shear zones near the walls (due to the flat walls) and hard spheres, the agreement

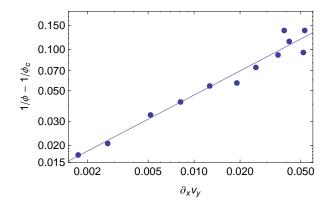

FIG. 16: Inverse of the volume fraction  $\phi$  in the glass (height of y = 125) versus the strain rate  $\partial_x v_y$  (along a cross-section going from the wall into center of the chute) using an asymptotic coefficient of restitution  $\mu_0$  of 0.97.

is still reasonable. This suggests that the results we have found are fairly robust to the details of the model.

## III. CONCLUSION

In this paper we investigated constitutive relations in the free-fall, fluid and glassy states observed in our simulations of granular matter. The pressure in all regions of the system where well described by what would be expected of a elastic hard sphere gas. However, the transport coefficients were distinctly different from what one would expect from kinetic theory. The viscosity and thermal conductivity increases with decreasing temperature in the fluid state, apparently diverging in the  $T \to 0$ limit. The thermal conductivity and dissipation were found in terms of the density, temperature and average collision frequency. The collision frequency in all sections was related to the pressure which is well described in terms of density and temperature. We also explored the static limit of the stresses in the glassy state and showed that values for the stresses in this region are almost entirely dependent on the collision directions. By providing closed expressions for the constitutive relations for the stresses, energy flux and dissipation, it is hoped that we have fulfilled our objective to provide useful constitutive relations that might be suitable for fully solving the stress tensor and the energy flux in granular flows. However, as granular systems are not in any sort of true equilibrium state further research is necessary to determine if the relations that were found to work well for our

chute simulations can be easily applied to other geometries.

Probably the most important aspect that has been neglected is the rotational degrees of freedom of the grains. The dissipation in these degrees of freedom from friction during a collision would give an additional factor that may give rise to anistropic stresses that often accompany granular flow. While frictionless bead packs can have macroscopic friction [27] the presence of microcopic static friction may still change the macroscopic observables. This will be an interesting point to investigate in future work.

- [26] We use units where the acceleration due to gravity g=1, the mean grain radius a=1, and the mean grain mass m=1. To convert to units where, say,  $g=9.8 \text{ m/s}^2$ ,  $a=1.5 \text{mm}=1.5 \times 10^{-3} \text{ m}$ , and  $m=0.11 \text{ grams}=1.1 \times 10^{-3} \text{ kg}$  (i.e. a steel ball with mass density of  $7850 \text{ kg/m}^3$ ), multiply our distance by a in meters, time

- by  $(a/g)^{1/2} = [(1.5 \times 10^{-3} \text{ m})/(9.8 \text{m/s}^2)]^{1/2} = 0.0124 \text{ s}$  and masses by m in kilograms. A typical simulation run is  $10^4 10^5$  time units, or 2 20 minutes of real time for a system made up of steel balls 3 mm in diameter. For a typical run with polydisperse grains, this corresponds to  $6.5 \times 10^9$  collisions.
